54 **Signal reproducing apparatus for optical recording and reproducing equipment and method for the same.**

57 The apparatus and method is used for recording optical information on an optical disk and reproducing the optical information therefrom by the use of an optical beam. The system is especially adapted to eliminate crosstalk from nearby tracks even when the position of the beam spot fluctuates with respect to a desired track and even when the size of a beam spot incident to the desired track is varied. The apparatus particularly comprises a frequency characteristic converter which receives output signals from a photodetector array (11). The photodetector array (11), for example, comprises 3 photodetectors (100, 101, 102) receiving input beams (130, 131 and 132). The photodetector (100) is associated with a desired track for reproducing a signal, whereas photodetectors (101, 102) are associated with neighbouring tracks for reproducing a replica of crosstalk. The frequency characteristic convertor (12) further comprises transversal filter means (110, 111, 112), each capable of controlling a frequency characteristic, an adder (120), a reference signal generator (121), an error detector (122), a filter control circuit

(123) for controlling the filters (110, 111, 112), a timing control circuit (124), a decision circuit (125), a switch (126) and an output terminal (133). The output of the photodetector (100) adapted to reproduce a signal is fed to the timing control circuit (124), which detects the beginning of a preamble signal written in the track beforehand and delivers a control signal to the reference signal generator (121) and switch (126). When the timing control circuit (124) detects the end of the preamble signal, it delivers a control signal to the reference signal generator (121) and switch (126). The characteristic control for the transversal filters (110, 111, 112) is sequentially performed on the basis of the preamble signal and the corresponding reference signal and on the basis of an input signal and an output signal of the decision circuit (125).

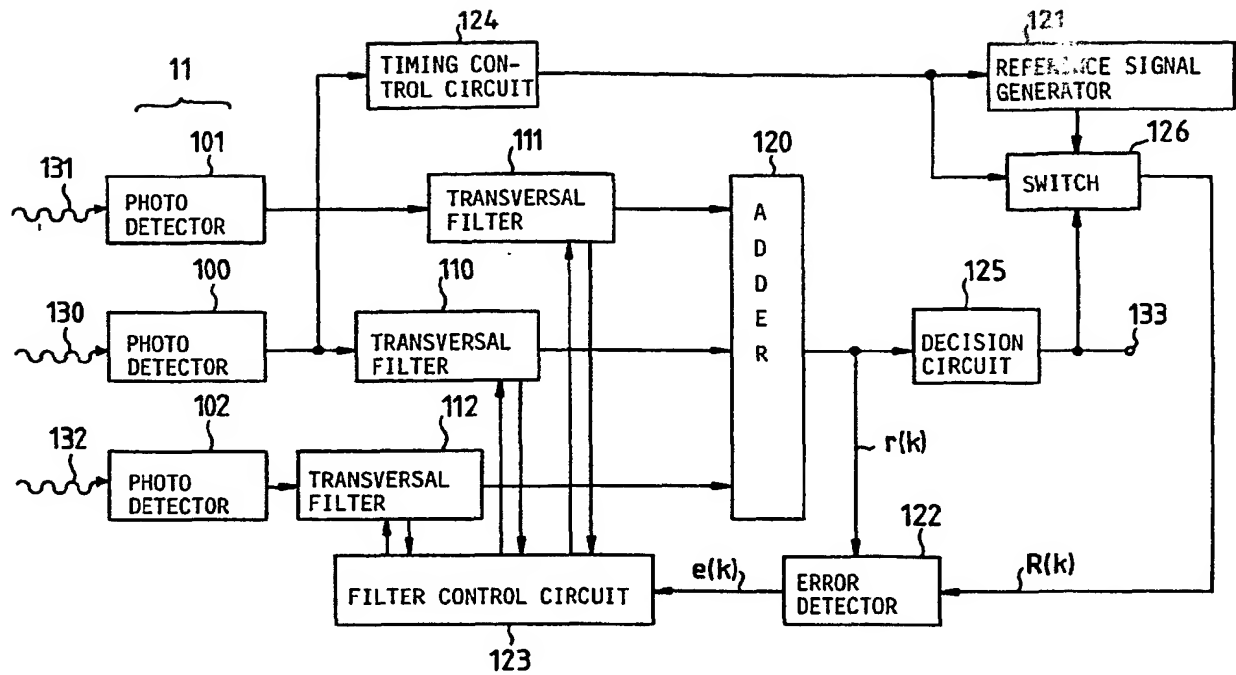

Fig. 2

SIGNAL REPRODUCING APPARATUS FOR OPTICAL RECORDING AND REPRODUCING EQUIPMENT AND METHOD FOR THE SAME

The present invention relates to an optical recording and reproducing apparatus which records optical information on an optical disk and reproduces the optical information therefrom by the use of an optical beam, and more particularly, to an apparatus and a method for reproducing information out of an optical recording disk. The optical disk is typically a magneto-optical medium and the information comprises data or audio/video information.

An optical recording/reproducing apparatus of this type is extensively used today because of its advantages that no physical contact is needed between an optical head for emitting a light beam and an optical disk in recording/reproducing operations, and random access is permitted. In recording, a light beam modulated by information strikes a disk to record it in the form of pits on a track of the disk, while the recorded information is reproduced by directing a light beam to the track and sensing the variation in the intensity of a reflection.

An optical recording and reproducing apparatus of the type described is apt to suffer from crosstalk from neighboring tracks and intersymbol interference from neighboring pits on the same track during playback mode operation. Specifically, when the spot of a light beam illuminating a track is enlarged to extend over to neighboring tracks or when the center of the spot is not coincident with that of a track, crosstalk occurs. When the spot of a light beam is enlarged to illuminate neighboring pits on the same track simultaneously, intersymbol interference occurs. These problems are more serious in the event of high-density recording wherein the distance between nearby tracks and the distance between nearby pits are extremely short.

An implementation for eliminating crosstalk from neighboring tracks is disclosed in Japanese Patent Laid-Open Publication No. 61-287056. This implementation is such that pilot signals each having a different frequency are recorded on respective tracks, e.g., three tracks, beforehand. Crosstalk amounts from neighboring tracks are determined by sensing a reflection of a light beam from a desired tracks and the neighboring tracks. Components of the pilot signals assigned to the neighboring tracks and contained in the reflection represent the crosstalk amounts. In playback operation, three light beams are directed respectively to the desired and neighboring tracks and three optical sensors including a main sensor sense respective reflections of the light beams from the tracks to reproduce respective signals. The signals from the sensors corresponding to the tracks neighboring the

desired track are controlled to produce reference levels corresponding to the amounts of crosstalk. Then, the signal from the main sensor for the desired tracks is processed, to produce a crosstalk-compensated reproduced signal by subtracting the reference levels from the signal from the main sensor. A problem with this prior art is that this crosstalk compensation is vulnerable to the displacement in location of light beam spots on the tracks and the fluctuation in size of the beam spots. Further, the prior art requires a more complicated structure since the pilot signal having a frequency different from that of a recorded signal should be interposed.

It is therefore an object of the present invention to provide a signal reproducing apparatus for use in optical recording and reproducing equipment, which is capable of sufficiently and adaptively eliminating crosstalk from nearby tracks even when the position of a beam spot fluctuates with respect to a desired track and even when the size of a beam spot incident to the desired track is varied.

In accordance with the present invention, in optical recording and reproducing equipment of the type using an optical head which emits a plurality of light beams onto different tracks on an optical recording disk and has a plurality of photodetectors for reproducing signals from reflections from the individual tracks, there is provided a signal reproducing apparatus comprising frequency characteristic converters respectively receiving the output signals from the photodetectors, an adder for adding converted output signals from the frequency characteristic converters to deliver a reproduced signal associated with a desired track, and converters each being capable of changing the frequency control means for adaptively controlling respective characteristics of the frequency characteristic converters so as to eliminate a crosstalk component from the reproduced signal.

The output signals of a plurality of photodetectors involving crosstalk and intersymbol interference each is fed to respective one of frequency characteristic converters (transversal filters) capable of changing the frequency characteristic independently of one another. The output of the frequency characteristic converter interconnected to the photodetector which receives a reflected light beam from a desired track is combined with the outputs of the other frequency characteristic converters interconnected to the other photodetectors which receive reflected light beams from neighboring tracks.

The frequency characteristic converter inter-

connected to the photodetectors for the desired track also has a function to remove intersymbol interference between nearby pits.

The crosstalk from a neighboring tracks is ascribable to the fact that a light beam spot for reproducing a signal from the desired track has certain extent and, therefore, partly reaches a neighboring track. Signal distortion caused by the crosstalk can be readily removed if a signal stored in the neighboring track which cause the crosstalk and characteristics of the light beam are known. In accordance with the present invention, a plurality of light beams each illuminates the desired track and the neighboring tracks are applied to read signals out of these tracks, and by using the signals read out of the neighboring tracks, a replica of the crosstalk contained in a desired signal is formulated.

In practice, the replica of crosstalk formulated on the basis of the signals read out of the neighboring tracks also includes crosstalk and intersymbol interference, causing distortions. Nevertheless, the distortions of the replica are negligible because they are second-order distortions with respect to the desired signal.

These frequency characteristic converters may be implemented as an L-tap transversal filter having baud rate (T) intervals. Assuming that three light beams and, therefore, three transversal filters as the frequency characteristic converters are used, the frequency characteristics of the individual transversal filters are achieved as follows. Previously, a predetermined preamble signal is written onto a disk, and when reproducing operation is started, the preamble signal is read out first. By using a reproduced output $r(k)$ corresponding to the preamble signal, which is produced by combining the outputs of the individual transversal filters and which involves crosstalk and intersymbol interference, and a reference signal sequence $R(k)$ equal to the preamble signal, tap coefficients of the individual transversal filters are updated by the following equations:

$$\vec{c}(k+1)_0 = \vec{c}(k)_0 + \beta(R(k) - r(k)) \vec{h}(k)_0 \quad (1)$$

$$\vec{c}(k+1)_1 = \vec{c}(k)_1 + \beta(R(k) - r(k)) \vec{h}(k)_1 \quad (2)$$

$$\vec{c}(k+1)_2 = \vec{c}(k)_2 + \beta(R(k) - r(k)) \vec{h}(k)_2 \quad (3)$$

where $\vec{c}(k)_0$ is a tap coefficient vector of the transversal filter associated with the desired track (the center beam) at a time k, and $\vec{c}(k)_1$ and $\vec{c}(k)_2$ are other tap coefficient vectors of the transversal filters associated with the neighboring tracks at the time k. Further, $\vec{h}(k)_0$, $\vec{h}(k)_1$ and $\vec{h}(k)_2$ are input signal vectors of the individual transversal filters, and β is a step size. In this case, $\vec{h}(k)_i$ and $\vec{c}(k)_i$ ($i = 0, 1, 2$) are L-dimensional

vectors and these vector's elements are respectively tap coefficients and output signals from registers in the transversal filter at the time k. While the step size β is generally determined in relation to the initial converging rate and followability required to the transversal filter, it may be selected in the range of about 0.001 to about 0.01.

By the above algorithm, when a sufficiently long preamble signal is used as a comparative signal, the tap coefficients of the individual transversal filters are so selected as to minimize the square error between $R(k)$ and $r(k)$. Furthermore, if the correlation between the preamble signal stored in the desired track and the preamble signal stored in the neighboring tracks is enough low, the characteristics of the transversal filters associated with the neighboring tracks are set such that the crosstalk from the neighboring tracks is cancelled. Since the reproduced output $r(k)$ is the sum of the outputs of the transversal filters, the characteristics of the transversal filters associated with the neighboring tracks are so set as to produce a replica of crosstalk components therefrom. With respect to the preamble signal, since low correlation between preamble signals of adjacent tracks is required, respective different preamble signals are previously assigned for adjacent tracks.

On the other hand, the characteristic of the transversal filter associated with the desired track is so set as to remove intersymbol interference from nearby pits on this track.

As stated above, the characteristics of individual frequency characteristic converters are set on the basis of signals read out from the desired track and the neighboring tracks, and the reproduced signal is produced by adding the outputs of the frequency characteristic converters. Hence, the reproduced signal becomes free from any crosstalk and intersymbol interference.

BRIEF DESCRIPTION OF THE DRAWINGS

The above and other objects, features and advantages will become more apparent from the following detailed description taken with the accompanying drawings in which:

Fig. 1 is a block diagram schematically showing a preferred embodiment of the present invention;

Fig. 2 is a schematic block diagram showing the construction of a frequency characteristic converter shown in Fig. 1;

Fig. 3 is a view representative of a relationship of three tracks and light beam spots on a recording disk;

Fig. 4 is a schematic block diagram showing a construction of a frequency characteristic con-

verter shown in Fig. 2;

Fig. 5 is a schematic block diagram showing a second embodiment of the present invention which uses a semiconductor laser emitting a single beam and a diffraction grating;

Fig. 6 is a schematic block diagram showing a third embodiment of the present invention which is implemented by a semiconductor laser emitting four beams;

Fig. 7 is a view showing a relationship of tracks and high beam spots on a disk particular to the embodiment of Fig. 6; and

Fig. 8 is a schematic block diagram showing a fourth embodiment of the present invention which uses a single photodetector and a signal holding circuit.

Referring to Fig. 1 showing a first embodiment of the present invention, a semiconductor laser array 1 emits three laser beams which are drivable independently of each other. The three laser beams are directed to different tracks on a recording medium (disk) 5 at the same time by way of a collimating lens 2 and a condensing lens 4 through a beam splitter 3. In a recording mode, the individual beams are modulated in intensity independently of one another to record data on their associated tracks.

The use of a plurality of light beams is a common practice with multi-track optical recording and reproducing equipment which records data on a plurality of tracks at the same time. An optical head for use in such equipment is taught in, for example, "Multi-Beam Magneto-Optical disk drive for Parallel read/write operation", presented at Optical Data Storage Topical Meeting, Society of Photo-Optical Instrumental Engineers, January 17-19, 1989.

In a reproducing mode, three beams reflected from the individual tracks on the disk 5 are separated by the beam splitter 3 to become incident to different photodetectors of a photodetector array 11 via a condensing lens 10. The output signals of the individual photodetectors are applied to a signal processing circuit 13 via a frequency characteristic converter 12 which features the present invention, as will be described in detail later. For tracking error detecting, the beams from the disk 5 are separated by a beam splitter 6 and then propagated through a condensing lens 7 to different photodetectors of a photodetector array 8. The outputs of the individual photodetectors of the array 8 are fed to a tracking error signal processing circuit 9. Such a construction allows signals stored in the tracks to be reproduced independently of each other, while allowing error signals to be detected also independently of each other. Furthermore, it is assumed that successive three tracks on the disk 5 previously store different preamble sig-

nals.

Fig. 2 shows parts of the photodetector array 11 and the frequency characteristic converter 12 in detail. There are shown in Fig. 2 a photodetector 100 associated with a desired track for reproducing a signal, photo-detectors 101 and 102 associated with neighboring tracks for producing a replica of crosstalk, transversal filters 110, 111 and 112 each capable of controlling a frequency characteristic, an adder 120, a reference signal generator 121, an error detector 122, a filter control circuit 123 for controlling the filters 110 to 112, a timing control circuit 124, a decision circuit 125, a switch 126, input beams 130, 131 and 132, and an output terminal 133.

Fig. 3 indicates a relationship between the beam spots and the tracks on the disk 5. As shown, beams 24a, 24b and 24c are incident to different tracks 21, 22 and 23, respectively. The intermediate spot 24b strikes a desired track 22 to pick up a signal from the desired track, while the end spots 24a and 24c strike the neighboring tracks adjacent to the desired track in order to reproduce the replica (compensating) signals for the signal read out of the desired track. The reference numeral 25 designates pits formed on the disk 5.

Referring back to Fig. 2, operation of the present invention will be described hereinafter. The input beams 130, 131 to 132 are incident to the photodetectors 100, 101 and 102, respectively which perform opto-electric conversion and process to produce digitized signals for the subsequent filtering process. The output of the photodetector 100 adapted to reproduce a signal is fed to the timing control circuit 124. In response, the timing control circuit 124 detects the beginning of a preamble signal written in the track beforehand and delivers a control signal to the reference signal generator 121 and switch 126. On reception of the control signal, the switch 126 is so conditioned as to apply the output signal of the reference signal generator 121 to the error detector 122. At this instant, the reference signal generator 121 feeds a reference signal identical to the preamble signal to the switch 126. When the timing control circuit 124 detects the end of the preamble signal, it delivers a control signal to the reference signal generator 121 and switch 126. In response, the reference signal generator 121 stops outputting the reference signal while the switch 126 is so conditioned as to couple the output of the decision circuit 125 to the error detector 122. It means that the characteristic control for the transversal filters 110, 111 and 112 is sequentially performed on the basis of the preamble signal and the corresponding reference signal at a first step and, at a second step, on the basis of the input signal and the output signal of

the decision circuit 125.

As shown in Fig. 4, the filters 110 to 112 may each be implemented by a 9-tap transversal filter, for example. In the filter, tap coefficient vector $\vec{c}(k)_{110}$ and input signal vector $\vec{h}(k)_{110}$ are supplied to the filter control circuit 123 and tap coefficient vector $\vec{c}(k+1)_{110}$ is received from the control circuit 123.

The signals involving the crosstalk and intersymbol interference are fed from the photodetectors 100, 101 and 102 to the filters 110, 111 and 112, respectively and the filters 110 to 112 delivers filtered resultant signals to the adder 120. At the same time, the filters 110 to 112 individually feed tap coefficient vectors $\vec{c}(k)_{110}$ to $\vec{c}(k)_{112}$ and input signal vectors $\vec{h}(k)_{110}$ to $\vec{h}(k)_{112}$ at the time k to the filter control circuit 123. The adder 120 sums the outputs of the filters 110 to 112 and delivers its output signal $r(k)$ at the time k to the decision circuit 125 and the error detector 122. The decision circuit 125 receives the input signal, which is a digital multi-level (multi-bit) signal at each sample point, and feeds a binary signal at each sample point as a final reproduced output signal through the output terminal 133. The decision circuit 125 also supplies its output to the switch 126. Receiving the outputs of the adder 120 and switch 126, the error detector 122 detects an error $e(k)$:

$$e(k) = R(k) - r(k)$$

where $r(k)$ and $R(k)$ are respectively the outputs of the adder 120 and switch 126 at the time k . The error $e(k)$ is fed from the error detector 122 to the filter control circuit 123. In this case, the error $e(k)$ is obtained by inhibiting the most significant bit (MSB) in the multi-bit signal from the adder 120. Namely, the error $e(k)$ is represented by the remaining bits except the MSB in the multi-bit signal from the circuit 120.

The filter control circuit 123 receives, at the time k , the tap coefficient vectors $\vec{c}(k)_{110}$ to $\vec{c}(k)_{112}$ and input signal vectors $\vec{h}(k)_{110}$ to $\vec{h}(k)_{112}$ from the filters 110 to 112 and the error $e(k)$ from the error detector 122. Then, the filter control circuit 123 determines the tap coefficient vectors $\vec{c}(k+1)_{110}$ to $\vec{c}(k+1)_{112}$ at a time $(k+1)$ as follows:

$$\vec{c}(k+1)_{110} = \vec{c}(k)_{110} + \beta e(k) \vec{h}(k)_{110} \quad (4)$$

$$\vec{c}(k+1)_{111} = \vec{c}(k)_{111} + \beta e(k) \vec{h}(k)_{111} \quad (5)$$

$$\vec{c}(k+1)_{112} = \vec{c}(k)_{112} + \beta e(k) \vec{h}(k)_{112} \quad (6)$$

wherein, β is representative of a predetermined step size. By equations (5) and (6), the filters 111 and 112 produce the replica of crosstalk from the neighboring tracks, in the reverse characteristic. The adder 1209 therefore, removes the crosstalk.

The equations (4), (5) and (6) correspond to the equations (1), (2) and (3). These tap coefficient vectors $\vec{c}(k+1)_{110}$ to $\vec{c}(k+1)_{112}$ are respectively fed to the filters 110 to 112 to control the

frequency characteristics of the individual filters 110 to 112. The input signal vector $\vec{h}(k)_{110}$ - ($\vec{h}(k)_{111}$, $\vec{h}(k)_{112}$) is fed to the filter control circuit 123 via terminals 606, while the tap coefficient vector $\vec{c}(k)_{110}$ ($\vec{c}(k)_{111}$, $\vec{c}(k)_{112}$) is delivered to the filter control circuit 123 via terminals 607. In response, the filter control circuit 123 outputs the tap coefficient vector $\vec{c}(k+1)_{110}$ - ($\vec{c}(k+1)_{111}$, $\vec{c}(k+1)_{112}$) via terminals 608, which has been updated by the equations (4), (5), (6)), respectively.

As described above, the tap coefficient control in the transversal filters is performed on the basis of the known preamble signal and the corresponding reference signal, at the first step. At the second step, such coefficient control is done on the basis of a recorded information signal. By the coefficient control at the second step, crosstalk compensation can be adaptively performed even when operation condition is varied. Further, it should be noticed that the tap coefficient control by using the known preamble signal at the first step is not essential for the present invention. Namely, if an error rate during a reproducing process is expected to be relatively low, it is possible to omit coefficient control on the basis of a known preamble signal at the first step. In other words, it is not necessary to record a known preamble signal and sufficient coefficient control for the crosstalk compensation can be adaptively performed only by the use of the recorded information signal.

Fig. 5 shows a second embodiment of the present invention in which a diffraction grating and a single light beam semiconductor laser are used instead of multi-light beam semiconductor laser. In the figure, the same or similar components are designated by like reference numerals as shown in Fig. 1. As shown, a single light beam emitted from the semiconductor laser 1 is supplied to a diffraction grating 41 to produce a plurality of light beams. In this embodiment, three light beams which are the zeroth-order and plus and minus first-order diffracted beams are produced. Other operations are performed in the same manner as described with Fig. 1.

Fig. 6 shows a third embodiment of the present invention in which a semiconductor laser array delivering four light beams are used. The relationship between beam spots and tracks on a disk 5 in this embodiment is shown in Fig. 7. Specifically, spots 852 and 853 are usable to reproduce signals. Therefore, the spots 851 and 853 are applied to remove crosstalk in association with the center spot 852 and the spots 852 and 854 are applied to remove crosstalk in association with the center spot 853. Since the third embodiment has the two spots for signal reproduction, two frequency characteristic converters 12, 12' each having the construction

shown in Fig. 2 are used. Reflections from the spots 851, 852, 853 and 854 on tracks 81, 82, 83 and 84, respectively, each is incident to respective one of four photodetectors of a photodetector array 11. In response, the photodetector array 11 produces signals 500, 501, 502 and 503. The frequency characteristic converter 12 receives the signal 501 for reproducing a signal and the signals 500 and 502 for removing crosstalk, while the frequency characteristic converter 12' receives the signal 502 for reproducing a signal and the signals 501 and 503 for removing crosstalk. The outputs of the frequency characteristic converters 12 and 12' are fed to signal processing circuits 13 and 13'.

Fig. 8 shows a fourth embodiment of the present invention in which a single photodetector 8 and a single photodetector 11' are used instead of the photodetector arrays of the other embodiments. Further, a holding circuit 14 for temporarily holding signals read out of individual tracks is provided before the frequency characteristic converter 12. Beam spots and tracks on a disk are the same as shown in Fig. 3. In a reproducing operation, three light sources are sequentially switched for each rotation of a disk so as to time-divisionally reproduce as signal from a desired track and signals from neighboring tracks which used for removing crosstalk. In order that all the signals necessary for the reproduction and the removal of crosstalk may be produced, a time period corresponding to three rotations of the disk is needed. The holding circuit 14, therefore, temporarily stores the signals reproduced from the individual tracks. This embodiment is successful in reducing the size of optical components, compared to the embodiments using photodetectors arrays.

In summary, it will be seen that the present invention provides a signal reproducing apparatus which on adaptively eliminate the crosstalk from neighboring tracks and thereby insures desirable reproduction of a recorded signal.

Claims

1. A signal reproducing apparatus for use in combination with an optical source for emitting a plurality of light beams directed to successive first and second tracks on a recording medium and a photodetector for receiving reflections of said light beams from said successive first and second tracks on said recording medium and for producing first and second signals, said signal reproducing apparatus comprising:

a plurality of characteristic converting means respectively receiving said first and second signals for varying frequency characteristics of said first and second signals to produce a first and second

characteristic-converted signals;

signal processing means for combining said first characteristic-converted signal and said second characteristic-converted signal to deliver a reproduced signal; and

characteristic control means for controlling a frequency characteristic of a said plurality of characteristic converting means in accordance with said reproduced signal.

2. A signal reproducing apparatus as claimed in claim 1, wherein said characteristic converting means is constructed by a transversal filter.

3. A signal reproducing apparatus as claimed in claim 1 or 2, wherein predetermined preamble signals are recorded in said successive first and second tracks on the recording medium; and said characteristic control means operates in response to detection of the preamble signal contained in said reproduced signal.

4. A signal reproducing apparatus as claimed in any of claims 1 to 3 wherein said characteristic control means includes

means for delivering a reference signal corresponding to the preamble signal associated with said center track;

means for detecting an error between said reference signal and the preamble signal contained in said reproduced signal;

means for controlling tap coefficients in said transversal filter in response to said error.

5. A signal reproducing apparatus as claimed in any of claims 2 to 4 further comprising decision means receiving said reproduced signal for delivering a binary signal representative of information recorded in said center track, wherein said characteristic control means includes

means for an error between said reproduced signal and said binary signal, and

means for controlling tap coefficients in said transversal filter in response to said error.

6. A signal reproducing method for an optical recording and reproducing system which uses an optical head for emitting a light beam onto successive adjacent tracks on a recording disk and delivering a first signal from a first track storing information to be reproduced and a second signal from a second track adjacent to said first track, said first and second tracks corresponding to said successive adjacent tracks, comprising:

filtering said first signal by a first transversal filter to produce a first filtered signal;

filtering said second signal by a second transversal filter to produce a second filtered signal;

adding said first and second filtered signals to an added signal;

binarizing said added signal into a binary signal representative of said information;

comparing said binary signal with said added sig-

nal to produce an error; and
controlling characteristics of said first and second
transversal filters in response to said error.

7. A signal reproducing method for an optical
recording and reproducing system which uses an
optical head for emitting a light beam onto succes-
sive adjacent tracks including a center track and a
side track and delivering a first signal from said
center track and a second signal from said side
track, said center and side tracks storing respective
preamble signals, comprising:
filtering said first signal by a first transversal filter
to produce a first filtered signal;
filtering said second signal by a second transversal
filter to produce a second filtered signal;
adding said first and second filtered signals to
produce an added signal;
generating a reference signal corresponding to the
preamble signal stored in said center track;
comparing a picked-up preamble signal contained
said added signal with said reference signal to
produce an error; and
controlling characteristics of said first and second
transversal filters in accordance with said error.

8. A signal reproducing apparatus for optical
recording and reproducing system which uses an
optical head for emitting a plurality of light beams
onto different tracks on a recording medium and
having a plurality of photodetectors for producing
first and second signals corresponding to reflec-
tions from said tracks independently of each other,
said apparatus comprising:
frequency characteristic converters each of varying
a frequency characteristic of respective one of re-
producing signals from said photodetectors inde-
pendently of each other;
combining means for combining outputs of said
frequency characteristic converters;
deciding means for executing decision of a signal
state on an output of said combining means;
preamble signal detecting means for detecting a
preamble signal out of an output of said predeter-
mined frequency characteristic converter;
reference signal outputting means for outputting a
reference signal in response to an output of said
preamble signal detecting means;
switch means coupled to said reference signal out-
putting means and said deciding means for de-
livering the reference signal when said preamble
signal detecting means detects the preamble signal
and an output of said deciding means when said
preamble signal detecting means does not detect
the preamble signal;
error signal outputting means for detecting an error
signal out of an output of said switch means and an
output of said combining means; and
control means for controlling characteristics of said
frequency characteristic converters.

W-8000 München 86(DE)(54) **Signal reproducing apparatus for optical recording and reproducing equipment and method for the same.**

(57) The apparatus and method is used for recording optical information on an optical disk and reproducing the optical information therefrom by the use of an optical beam. The system is especially adapted to eliminate crosstalk from nearby tracks even when the position of the beam spot fluctuates with respect to a desired track and even when the size of a beam spot incident to the desired track is varied. The apparatus particularly comprises a frequency characteristic converter which receives output signals from a photodetector array (11). The photodetector array (11), for example, comprises 3 photodetectors (100, 101, 102) receiving input beams (130, 131 and 132). The photodetector (100) is associated with a desired track for reproducing a signal, whereas photodetectors (101, 102) are associated with neighbouring tracks for reproducing a replica of crosstalk. The frequency characteristic converter (12) further comprises transversal filter means (110, 111, 112), each capable of controlling a frequency char-

acteristic, an adder (120), a reference signal generator (121), an error detector (122), a filter control circuit (123) for controlling the filters (110, 111, 112), a timing control circuit (124), a decision circuit (125), a switch (126) and an output terminal (133). The output of the photodetector (100) adapted to reproduce a signal is fed to the timing control circuit (124), which detects the beginning of a preamble signal written in the track beforehand and delivers a control signal to the reference signal generator (121) and switch (126). When the timing control circuit (124) detects the end of the preamble signal, it delivers a control signal to the reference signal generator (121) and switch (126). The characteristic control for the transversal filters (110, 111, 112) is sequentially performed on the basis of the preamble signal and the corresponding reference signal and on the basis of an input signal and an output signal of the decision circuit (125).
